Gastaldelli, Amalia, Michele Edmìn, Fabrizio Conforti, Stefania Camasta, and Ele Ferrannini. Insulin prolongs the QTc interval in humans. *Am J Physiol Regulatory Integrative Comp Physiol* 279: R2022–R2025, 2000.—Insulin hyperpolarizes plasma membranes; we tested whether insulin affects ventricular repolarization. In 35 healthy volunteers, we measured the Q-T interval during electrocardiographic monitoring in the resting state and in response to hyperinsulinemia (euglycemic 1-mU·min⁻¹·kg⁻¹ insulin clamp). A computerized algorithm was used to identify T waves; Bazett’s formula was employed to correct Q-T (QTc) by heart rate (HR). In the resting state, QTc was inversely related to indexes of body size (e.g., body surface area, \( r = -0.53, P < 0.001 \)) but not to indexes of body fatness. During the clamp, HR (67 ± 1 to 71 ± 1 beats/min, \( P < 0.0001 \)) and plasma norepinephrine levels (161 ± 12 to 184 ± 10 pg/ml, \( P < 0.001 \)) increased. QTc rose promptly and consistently, averaging 428 ± 6 ms between 30 and 100 min (\( P = 0.014 \) vs. the resting value of 420 ± 5 ms). Fasting serum potassium (3.76 ± 0.03 mM) declined to 3.44 ± 0.03 mM during insulin. After adjustment for body size, resting QTc was directly related to fasting plasma insulin (partial \( r = 0.43, P = 0.01 \)) and during insulin stimulation (partial \( r = -0.47, P = 0.003 \)). Neither resting nor clamp-induced QTc was related to insulin sensitivity. Physiological hyperinsulinemia acutely prolongs ventricular repolarization independent of insulin sensitivity. Both insulin-induced hypokalemia and adrenergic activation contribute to this effect.

**METHODS**

Thirty-five normotensive volunteers were studied (Table 1). All had normal oral glucose tolerance, liver, renal, and endocrine function tests; none were taking any medications. The investigation was approved by the Institutional Review Board, and all subjects gave informed consent.

Body composition was evaluated by electrical bioimpedance. Each subject received a euglycemic insulin clamp, which was carried out after an overnight (12–14 h) fast and consisted of 100 min of insulin infusion at a rate of 1 mU·min⁻¹·kg⁻¹ (6). A polyethylene catheter was inserted into an antecubital vein for the infusion of glucose and insulin. Another catheter was threaded into a wrist vein retrogradely, and the hand was placed in a heated box (−60°C) for the sampling of arterialized blood. After instrumentation, the subjects rested at least 30 min in the supine position; the following 40 min constituted the basal period. Throughout the study, electrocardiographic recording was performed with the use of a bipolar lead frequency-modulation system (Remco-Cardioline, Milano, Italy) and both an inferior and a precordial lead.

cose and insulin concentrations as well as with glucose levels measured after oral glucose loading (7). On these grounds, it was postulated that hyperinsulinemia and/or glucose intolerance were causally related to a long Q-T. Direct proof of insulin or glucose effects on Q-T is, however, lacking.

Insulin exerts a prompt powerful action to increase transmembrane potential (25). After application of physiological amounts of insulin, the electrical potential across the plasma membrane of adipocytes, skeletal, and cardiac myocytes increases by a few millivolts due to the accumulation of negative charges on the inner side of the membrane (26). Because the Na⁺⁻K⁺ pump is electrogenic, stimulation of Na⁺⁻K⁺-ATPase could explain insulin-induced hyperpolarization. In excitable cells, such as cardiac myocytes, the predicted functional consequence of insulin-induced hyperpolarization is a lengthening of the repolarization phase. The present study was undertaken to directly test this hypothesis by measuring the Q-T interval in nondiabetic volunteers in the resting condition and during euglycemic hyperinsulinemia.

Insulin prolongs the QTc interval on the electrocardiogram (ECG) measures the duration of repolarization of ventricular myocardium. A long Q-T signals an increased risk for arrhythmias (4) and sudden death (2), particularly in postinfarction patients (1) but also in apparently healthy people (20). The Q-T interval is characteristically prolonged in diabetes and has been related to unexplained cases of sudden overnight death in diabetic patients on insulin treatment (10). Q-T lengthening has been reported in other insulin-resistant states such as obesity (9). In a population-based survey, Q-T prolongation was associated with fasting plasma glucose and insulin concentrations as well as with glucose levels measured after oral glucose loading (7). On these grounds, it was postulated that hyperinsulinemia and/or glucose intolerance were causally related to a long Q-T. Direct proof of insulin or glucose effects on Q-T is, however, lacking.

In six subjects, the study was repeated on a different day (in randomized order to the clamp) with the use of an identical protocol, except that the insulin infusion was replaced by a saline infusion. At the end of the 100-min infusion, subjects were asked to stand up and then resume the supine position over a period of 5 min.

ECG processing. The ECG was digitized at 250 samples/s with a 12-bit/sample precision and stored in a binary format. The selected 250-Hz frequency allows detection of R-R oscillations up to 4 ms. The ECG was processed with the use of extensively tested algorithms (23) to detect the QRS complex and the R-wave reference point by a derivative/amplitude criterion, without interpolation of the original signal. For the Q-T interval, a computerized algorithm was used to identify the onset of QRS and the end of the T wave on the precordial lead (with the use of a derivative filter applied to an observation interval on the ECG signal centered on the theoretical trend 0.4×R-R1/2, on the basis of threshold-trespassing deflection with reference to the baseline signal) (23). Q-T varies inversely with the heart rate (HR); the duration of recovery decreases as the rate of activation increases. For this reason, Q-T is corrected with reference to the baseline signal (23). Q-Tc was similar in men and women and was unrelated to BMI. Baseline plasma epinephrine concentrations (31±4 μg/ml) did not change after insulin (37±8 μg/ml), whereas plasma norepinephrine levels rose (from 161±12 to 184±10 pg/ml, P<0.001). Fasting serum potassium concentrations (3.76±0.03 mEq/l) declined to 3.44±0.03 mEq/l (P<0.0001) during the 40- to 100-min time period of insulin administration.

In bivariate regression adjusting for BSA, resting QTC was directly related to fasting plasma insulin concentrations (Fig. 2); an inverse association with M values fell short of statistical significance. After adjustment for BSA, QTC values were reciprocally related to serum potassium concentrations both in the basal condition and during insulin administration (Fig. 2).

**RESULTS**

At rest (between time −40 and 0 min), HR averaged 67±1 beats/min and QTC 420±5 ms. In women, QTC tended to be longer than in men (425±6 vs. 411±8 ms, P=0.1). In univariate analysis, QTC was inversely related to indices of body size (body weight, r = −0.40, P<0.02; body surface area (BSA), r = −0.51, P<0.002; fat-free mass, r = −0.46, P<0.01), whereas it was unrelated to indices of body fatness [body mass index (BMI), fat mass, percent fat mass], plasma catecholamine levels, or the M value.

During the clamp, HR increased significantly (to an average of 71 beats/min between 30 and 100 min, P<0.0001); QTC increased in a similar time course to HR (to an average 428±6 ms between 30 and 100 min, P=0.014) (Fig. 1). The insulin-induced increase in QTC was similar in men and women and was unrelated to BMI. Baseline plasma epinephrine concentrations (31±4 μg/ml) did not change after insulin (37±8 μg/ml), whereas plasma norepinephrine levels rose (from 161±12 to 184±10 pg/ml, P<0.001). Fasting serum potassium concentrations (3.76±0.03 mEq/l) declined to 3.44±0.03 mEq/l (P<0.0001) during the 40- to 100-min time period of insulin administration.

In bivariate regression adjusting for BSA, resting QTC was directly related to fasting plasma insulin concentrations (Fig. 2); an inverse association with M values fell short of statistical significance. After adjustment for BSA, QTC values were reciprocally related to serum potassium concentrations both in the basal condition and during insulin administration (Fig. 2).

![Fig. 1. Time course of heart rate (top), Q-T interval (middle), and QTc (bottom) during resting conditions and during 100 min of euglycemic hyperinsulinemia in 35 nondiabetic subjects.](http://ajpregu.physiology.org/ by 10220.335 on June 4, 2017)
In the time-control experiments, there was no significant change in either HR or Q-T (data not shown). Standing up resulted in tachycardia (to a peak of 77 \( \pm \) 2 beats/min, \( P = 0.0001 \)), which was accompanied by a rise in QTc (to 454 \( \pm \) 6 ms, \( P = 0.0001 \)).

DISCUSSION

The present study demonstrated that acute physiological hyperinsulinemia prolongs the QTc interval. This effect 1) was prompt, being already fully established after 30 min of insulin infusion (Fig. 1); 2) did not differ in men vs. women, nor was it dependent on obesity; and 3) was unrelated to insulin-mediated glucose uptake. The finding explains previous observations that QTc lengthens after a meal in concomitance with a rise in HR (15). In addition, the fact that it is the hyperinsulinemia, rather than insulin resistance, that is responsible for QTc prolongation makes it possible to extrapolate this acute effect of insulin to a chronic condition. In fact, in insulin-resistant individuals, compensatory hyperinsulinemia may act unopposed on membrane polarization, thereby leading to persistent QTc lengthening. In keeping with this prediction, QTc has been found to be prolonged in states of insulin resistance, such as diabetes and obesity, even in the absence of autonomic neuropathy (9, 10). Our finding (Fig. 2) that the resting QTc was positively related to the degree of fasting hyperinsulinemia lends further support to this interpretation.

With regard to the mechanism of insulin-induced hyperpolarization, the finding that QTc and serum potassium levels were reciprocally related suggests that stimulation of cellular potassium uptake is the common mechanism for both insulin-induced hyperpolarization and insulin-induced hypokalemia. In studies employing the perfused forearm technique, we have shown that insulin stimulates potassium uptake by forearm tissues in a manner that is ouabain inhabitable and independent of concomitant forearm glucose uptake (8). Pertinent in this regard is the evidence from in vitro studies in mollusks that extracellular application of insulin directly hyperpolarizes neurons of the abdominal ganglion (22). Thus in both excitable and nonexcitable cells, insulin acts directly on the cell membrane to shift extracellular potassium into the cytoplasm, thereby hyperpolarizing the membrane (8, 22, 25, 26). In excitable tissues, hyperpolarization prolongs the repolarization phase either by increasing the temporal dispersion of action potential recovery or through early afterdepolarizations (12).

Q-T lengthening can also result from adrenergic activation; as in the case of insulin, this effect is mediated by hypokalemia, indicating sympathetic stimulation. This phenomenon results from a stimulatory action of insulin on midbrain nuclei that dispatch excitatory impulses to sympathetic neurons and inhibitory influences to the vagus (21). Thus physiological hyperinsulinemia reinforces its effect on membrane potential and serum potassium concentrations via sympathetic activation.

In conclusion, physiological hyperinsulinemia causes QTc prolongation both directly and through sympa-
thetic activation, the common mechanism (and manifestation) being the transfer of potassium ions from the extracellular to the intracellular space.

**Perspectives**

The present results can be integrated with existing information to delineate a complex feedback system (Fig. 3) regulating a number of vital functions. In this system, plasma insulin and adrenergic activity are hormonal effectors, serum potassium concentrations constitute a common interacting relay, and membrane potential is the output. Thus both plasma insulin and catecholamines lower serum potassium by promoting its uptake into cells (5, 8). On the other hand, insulin enhances adrenergic activity, whereas adrenergic stimulation (mostly through α2 receptors), in turn, inhibits insulin release (16). The physiological operation of this system is best illustrated by the response to feeding. The rise in circulating insulin activates the sympathetic branch of the autonomic nervous system, thereby preparing the hemodynamic (e.g., splanchic vasodilatation) and thermogenic adaptation to feeding. Together with catecholamines, insulin stores alimentary potassium by transferring it into cells as well as sparing it from urinary loss. This ionic shift and other direct membrane effects of insulin (26) hyperpolarize cell membranes, thereby strengthening their refractoriness to electrical stimuli. One consequence of this membrane change in the cardiovascular system is a prompt reduction in HR variability (14). Another one is attenuation of adrenergic-mediated vascular smooth muscle cell contraction (19). The serum level of potassium is set to serve as a modulator of the combined action of insulin and catecholamines. Thus hypokalemia depresses the insulin-secretory response to glucose (17), whereas hyperkalemia downregulates sympathetic activity (13).

A key element of this physiological system is that it is not tied with insulin’s actions on glucose metabolism. In fact, the effects of insulin on serum potassium (8), HR variability (14), and membrane polarization (as shown in the present work) are all independent of insulin-mediated glucose utilization. Therefore, in insulin-resistant states in which chronic hyperinsulinemia ensues as a compensatory response, the membrane effects of insulin are not attenuated by insulin resistance. Consequently, the risk of cardiac arrhythmias is enhanced; this may constitute one basis for the increased cardiovascular risk of insulin-resistant states (11).
