Taylor, Norman E., and Allen W. Cowley, Jr. Effect of renal medullary H₂O₂ on salt-induced hypertension and renal injury. Am J Physiol Regul Integr Comp Physiol 289: R1573–R1579, 2005.—There is growing evidence of increased arterial vascular oxidative stress in both genetic (32, 33) and induced forms of hypertension (2, 8, 37), suggesting that reactive oxygen species (ROS) may contribute to the pathogenesis of this disease. Although most of these studies have focused on the ability of superoxide (O₂⁻) to scavenge and inactivate nitric oxide (NO), recent evidence suggests that ROS other than O₂⁻ produce hypertension by mechanisms independent of NO. The present study examines the role of the ROS hydrogen peroxide (H₂O₂) in the development of salt-sensitive (SS) hypertension.

Evidence that H₂O₂ could participate in hypertension was obtained in transgenic mice that overexpressed the human catalase gene (38). These mice showed significantly blunted arterial pressure and aortic H₂O₂ compared with wild-type mice in response to chronic infusions of norepinephrine or angiotensin II. In addition to catalase, glutathione peroxidase plays a key role in scavenging H₂O₂ in vivo. When the substrate of this enzyme, glutathione, was depleted in Sprague-Dawley (SD) rats, mean arterial pressure (MAP) increased significantly (9). Conversely, n-acetyl-l-cysteine, a well-known antioxidant that can increase glutathione stores, prevented the salt-induced hypertension of Dahl S rats when it was supplemented in the chow (40).

Studies in our laboratory in SD rats have found that local excess production of H₂O₂ within the medulla of the kidney would produce hypertension. In one of these studies, chronic renal medullary infusion of the O₂⁻ dismutase (SOD) inhibitor, diethyldithiocarbamic acid, into a single remaining kidney produced hypertension (21). Co-administration of the SOD mimetic, tempol, failed to prevent this hypertension and only with the addition of catalase was hypertension attenuated (22). Because tempol was shown to inhibit the diethyldithiocarbamic acid-induced elevations of medullary O₂⁻, as determined by microdialysis, the anti-hypertensive actions of catalase indicated a role for H₂O₂ in maintaining hypertension in this model. Insight into the mechanisms of these H₂O₂ responses was provided in a second study when acute interstitial infusion of H₂O₂ reduced medullary blood flow and sodium excretion, and these dose-dependent responses were reversed by catalase treatment (3). A third study then showed that chronic renal medullary interstitial (ri) infusion of H₂O₂ (1.0–1.4 μmol·kg⁻¹·min⁻¹) produced chronic hypertension in SD rats. Microdialysis studies conducted after day 5 of infusion found that renal interstitial H₂O₂ was nearly five times higher than saline-infused rats (22).

Although these studies demonstrated that elevations of H₂O₂ in the renal medulla could induce hypertension, the significance of endogenously produced H₂O₂ in this region of the kidney that may occur in genetic forms of hypertension remains to be established. The present study examined the role H₂O₂ produced within the renal medulla of SS rats might play in the development of salt-induced hypertension and related renal end-organ damage. SS rats were compared with an inbred consomic control strain, in which chromosome 13 of the Brown Norway rat was introgressed onto the genetic background of the SS rat (SS-13BN). This strain exhibits only a 30% difference from the SS/Medical College of Wisconsin (MCW) rat over the whole genome, compared with 30% for the Dahl salt-resistant rat (R), yet exhibits more than...
a 50% reduction of salt-induced hypertension, proteinuria, and glomerular disease (4).

The aims of the present study were twofold: 1) to determine whether SS rats exhibit greater levels of oxidative stress, as reflected by \( \text{H}_2\text{O}_2 \) in the renal medulla, relative to consomic SS-13\textsuperscript{BN} rats; and 2) to determine the role that \( \text{H}_2\text{O}_2 \) within the renal medulla plays in salt-induced hypertension and renal injury in SS rats. Catalase was therefore infused chronically into the ri of SS rats fed a high (4%) NaCl diet to examine its effects on MAP, medullary \( \text{H}_2\text{O}_2 \), and kidney damage. Conversely, \( \text{H}_2\text{O}_2 \) was infused ri into SS-13\textsuperscript{BN} rats fed a 4% NaCl diet to determine whether the trait of SS hypertension could be exacerbated in this strain. Microdialysis was used to collect samples of renal medullary interstitial \( \text{H}_2\text{O}_2 \) in each of these studies.

**METHODS**

Animal preparation. Experiments were performed on inbred lines of male Dahl SS/\textit{H}s\textit{d}M\textit{c}w\textit{i} (SS) and consomic SS-13\textsuperscript{BN} rats maintained as inbred colonies at the MCW (4). The MCW Institutional Animal Care and Use Committee approved all experimental protocols. Rats were maintained ad libitum on tap water, and a purified AIN-76A rodent diet containing 0.4% or 4% NaCl (Dyets, Bethlehem, PA).

Male SS and SS-13\textsuperscript{BN} rats fed a 0.4% NaCl diet were uninephrectomized at 9 wk of age. After a 7- to 10-day recovery period, medullary interstitial and femoral arterial catheters were implanted as previously described (24). Five to six days later, daily 3-h measurements of MAP were begun using an online data collection and analysis system (5).

After the last day of blood pressure recording, acute surgical preparation for in vivo microdialysis of the left kidney was performed as described previously (21). After a 2-h equilibration period, dialysate effluent was collected over two 30-min intervals and renal medullary interstitial \( \text{H}_2\text{O}_2 \) concentrations \((\text{[H}_2\text{O}_2\text{]})\) were determined by fluorescence spectrometry using the Amplex Red \( \text{H}_2\text{O}_2 \), Assay Kit (Molecular Probes, Eugene, OR).

**Group 1.** Eleven-week-old SS and SS-13\textsuperscript{BN} rats were prepared as in Fig. 1. Renal medullary interstitial \( \text{H}_2\text{O}_2 \) was also measured in each of these studies.

**RESULTS**

**Group 1: renal medullary interstitial \( \text{H}_2\text{O}_2 \) in rats fed a 0.4% NaCl diet.** SS rats exhibited higher MAP (126 ± 3 mmHg, \( n = 7 \)) than SS-13\textsuperscript{BN} rats (116 ± 2 mmHg, \( n = 7 \)), even when these rats were fed a 0.4% NaCl diet from weaning, as shown in Fig. 1. Renal medullary interstitial \( \text{H}_2\text{O}_2 \) was also found to be significantly higher in SS compared with SS-13\textsuperscript{BN} rats (145 ± 17 nM, \( n = 7 \) vs. 56 ± 14 nM, \( n = 7 \)).
Group 2: effect of renal medullary interstitial infusion of catalase on salt-induced hypertension and medullary H2O2 concentration in SS rats. Catalase was infused chronically into the renal medulla of SS rats to determine the contribution of medullary H2O2 production to salt-induced hypertension. As summarized in Fig. 2, MAP of the saline-infused control group increased from 129 ± 2 to 163 ± 4 mmHg after 5 days of high salt (4%), whereas MAP in SS rats infused with catalase increased from 122 ± 1 to only 146 ± 2 mmHg after 5 days of high salt. At the end of 5 days, renal medullary [H2O2] in saline-infused rats averaged 297 ± 52 nM (n = 7) and was significantly reduced (96 ± 41 nM, n = 7) in catalase-infused rats. These data show that medullary production of H2O2 contributes importantly to the salt-induced hypertension in the SS rat.

Group 3: effect of renal medullary interstitial infusion of H2O2 on salt-induced hypertension and medullary [H2O2] in SS-13BN rats. To further evaluate the importance of H2O2 in salt-induced hypertension, renal medullary [H2O2] was increased in relatively salt-insensitive SS-13BN rats to determine whether the SS trait of salt sensitivity could be restored in this consomic strain (Fig. 3). H2O2 was infused at a dose that did not change MAP over 3 days on a 0.4% salt diet (347 nmol·kg⁻¹·min⁻¹). When the salt in the diet was increased from 0.4 to 4%, MAP increased 25 mmHg (from 120 ± 2 to 145 ± 2 mmHg). In saline vehicle-infused SS-13BN rats, MAP increased only 16 mmHg (118 ± 2 to 134 ± 1 mmHg) when fed the high-salt diet. As determined by microdialysis at the end of the experiment, saline-infused SS-13BN rats exhibited H2O2 concentrations of 44 ± 9 nM (n = 6) compared with 83 ± 11 nM for H2O2-infused rats (n = 6). Renal medullary [H2O2] levels were highly correlated with MAP in the three experimental groups (r = 0.602, P < 0.001). Of particular note, SS rats infused with catalase exhibited the same level of hypertension as the H2O2-infused SS-13BN rats (146 ± 2 vs. 145 ± 2 mmHg) and also had similar levels of renal medullary H2O2 (96 ± 41 vs. 83 ± 11 nM). Blood pressure salt sensitivity was exacerbated in the consomic SS-13BN simply by elevating medullary H2O2, indicating that excess H2O2 production in this region of the kidney contributes to salt-induced hypertension in SS rats.

Histological quantification of tubular necrosis and interstitial fibrosis. The percentage of the outer medulla exhibiting protein casts was used as an index of tubular necrosis. As shown in Fig. 4, cast formation in SS rats receiving catalase infusions (7.5 ± 1.0%, n = 6) was significantly less than saline-infused controls (16.0 ± 2.0%, n = 6). Despite considerable reduction of tubular damage, catalase-infused SS rats continued to exhibit significantly more tubular casts than the
saline-infused SS-13BN rats. There was no significant difference in cast staining between saline and H2O2-infused SS-13BN rats (4.7 ± 0.6%, n = 6 vs. 6.0 ± 1.3%, n = 6). Tubular necrosis was significantly correlated to MAP (r = 0.83, P < 0.05).

The percentage of tissue that stained positive for α-SMA in the outer medulla was used as an early index of interstitial fibrosis. SS rats receiving the medullary infusion of catalase exhibited significantly reduced SMA staining (0.6 ± 0.2%, n = 6) compared with saline-infused SS rats (2.3 ± 0.6%, n = 6), as shown in Fig. 5. Conversely, SS-13BN rats that were infused with H2O2 and fed a 4% NaCl diet exhibited an elevated α-SMA staining compared with saline-infused controls (2.8 ± 0.7%, n = 6 vs. 0.7 ± 0.2%, n = 6). Taken together, these observations indicate that elevations of H2O2 contribute to the development of medullary interstitial fibrosis.

DISCUSSION

The present study examined whether H2O2 levels are elevated in SS rats and tested the hypothesis that increased renal medullary H2O2 in this strain contributes to salt-induced hypertension and renal injury. The results indicate that H2O2 is elevated in the renal interstitium of SS rats compared with the consomic SS-13BN control strain and that arterial pressures were significantly elevated in the SS, even before the introduction of a high-salt diet. Renal interstitial infusion of catalase in the SS significantly reduced H2O2 levels and greatly attenuated the salt-induced increase in arterial pressure. Conversely, increasing renal medullary H2O2 in SS-13BN rats increased the salt sensitivity. This suggests that the gene(s) protecting the SS-13BN from increased oxidative stress may also be responsible for the protection from salt-induced hypertension.
Reduction of medullary H₂O₂ in SS rats also significantly reduced renal injury as measured by a reduction in protein casts and α-SMA staining in the outer medulla. Tubulointerstitial fibrosis and capillary injury occur first in the outer medulla and juxtamedullary glomeruli in many forms of experimental hypertension, including Dahl S rats (16), and is considered a final common pathway of progressive kidney disease. Myofibroblasts, which contain α-SMA (20), are rarely found in the normal kidney, and when they become detectable in the interstitium, collagen deposition accumulates in the areas in which they reside (1), making α-SMA staining an important early index of interstitial fibrosis. α-SMA staining was significantly increased in SS-13BN rats infused with H₂O₂, suggesting that this ROS could play a significant role in initiating interstitial fibrosis in the kidney. These data support a role for H₂O₂ in the maintenance of salt-induced arterial pressure and renal injury in the SS rat.

Consomic SS-13BN rats as a control for SS rats. The selection of appropriate controls for the Dahl S and other hypertensive strains has been constrained by the absence of available methods to carry out extensive whole genome scans. Control strains for hypertension have been generally selected on the basis of the ancestral origins of the strains, even though all of the traditional “control” strains (Wistar-Kyoto, Dahl R, etc.) are now known to exhibit considerable genetic divergence from the hypertensive strains. This results in hundreds of phenotypic differences between the control and hypertensive strains, most of which are unrelated to the pathogenesis of hypertension. In support of this argument, there is a 77% allelic difference between Brown-Norway/MCW and SS/MCW rats.
a 48% difference between spontaneously hypertensive and Wistar-Kyoto rats, a 52% difference between SD and SS/MCW rats, and a 30% difference between Dahl R and SS/MCW rats as assessed by whole genome scans using 1,541 microsatellite markers (13). In contrast, the consomic SS-13BN rat exhibits only a 1.95% allelic difference from SS/MCW rats over the entire genome, and yet salt-induced hypertension, proteinuria, and glomerular disease is greatly reduced (4). Based on our genetic analysis, we believe that the SS-13BN rat is currently the best available control strain for phenotypic comparison with the SS/MCW rats because it possesses less genetic difference than any other available strain.

Salt sensitivity and renal medullary oxidative stress. SS rats have been shown to be deficient in NO (34) and 20-HETE (15), while also exhibiting increased sympathetic tone (14) and oxidative stress (25, 26, 33), all of which contribute to the salt sensitivity of this strain. This study provides direct evidence of increased oxidative stress within the renal medulla of the SS rat and supports indirect measurements made by others. Studies where tempol attenuated salt-induced hypertension in SS rats (12, 25) support a role for O2•− in maintaining elevated pressure in this strain. However, just as in our diethyldithiocarbamatic acid model of hypertension, administration of tempol was not fully protective. Indeed, Williams et al. (36) observed that tempol administered in the drinking water of SD rats was unable to suppress the inhibition of hypertension produced by ET1 receptor blockade plus a high-salt diet and that this was accompanied by increased urinary H2O2 excretion. The purpose of this study was to determine whether H2O2 within the renal medulla of SS rats plays a role in salt-induced hypertension and renal injury separate from the direct effects of other ROS.

Increased H2O2 concentrations in the renal medulla of SS rats may be due to increased production or decreased scavenging of this ROS. H2O2 is a relatively stable species that diffuses freely into cells and is thought to be generated predominately from the SOD dismutation of O2•−, although it can also be produced directly by certain oxidases, such as glucose oxidase, through a two-electron reduction of O2 (31). Evidence suggests that NADPH oxidase is an important source of ROS in hyper-tension (17), playing an especially important role in tubular O2•− production in the renal medulla (41). Renal cortical protein and mRNA levels of the NADPH oxidase subunit p47phox were shown to be higher in Dahl S than Dahl R rats when fed an 8% NaCl diet, and this increase could be attenuated by either administration of an angiotensin-converting enzyme inhibitor (35), L-arginine (7), or N-acetyl-L-cysteine (40). Studies have begun to assess the role that ROS scavengers play in the kidneys of SS rats. A study by Meng et al. (26) showed that the Dahl S rat has lower renal SOD levels compared with Dahl R rats. This question was also recently addressed in DNA microarray studies to determine differential gene expression in renal outer medullary tissue of SS and SS-13BN rats fed a 0.4 or 4% NaCl diet. Although these data did not resolve whether NADPH oxidase enzyme subunits were differentially expressed, no difference was found in the expression of SOD, catalase, glutathione peroxidase, and synthetase along with several genes related to the biopinter pathway. Glutathione-S-transferase and peroxiredoxin-6 (1-Cys peroxiredoxin) were differentially expressed between SS and SS-13BN rats, although they were expressed lower in the SS-13BN rats. It is now important to follow up these studies by measuring the activities of the enzymes contributing to H2O2 synthesis/degrada-

It is presently unknown what gene or set of genes on chromosome 13 protect the consomic SS-13BN rat from oxidative stress. Cyclooxygenase-2 is located on chromosome 13 and is a potential source of O2•−. Administration of the selective cyclooxygenase-2 inhibitor, celecoxib, was found to modestly decrease salt-induced hypertension in the Dahl S rat and significantly reduce plasma 8-isoprostane levels (11), suggesting a possible role for the gene in this model of hypertension. Currently, the genetic basis responsible for the protection afforded by BN chromosome 13 remains to be established.

Role of H2O2 in hypertension. The role that H2O2 plays in vascular function and hypertension is just beginning to be studied. H2O2 has been shown to be both a vasodilator and a vasoconstrictor. It has been implicated as an endothelial-derived dilating factor in both animal and human studies based on observations that catalase inhibited dilation of mesenteric arteries from endothelial NO synthase knockout mice (23) and in human coronary arterial microvessels (27). This response has been attributed to membrane hyperpolarization through the activation of calcium-dependent K+ channels (27). In contrast, studies in several different vascular beds have reported that H2O2 acts as a vasoconstrictor (28, 30, 39). Aortic contraction was found to be Ca2+ independent with evidence that hydroxyl radicals, cyclooxygenase products, protein kinase C, and products of protein tyrosine phosphorylation may play some role in these responses (39).

Recent studies in mesenteric arteries (10) and rat gracilus arterioles (6) provide some insight into these discrepancies by showing that responses to H2O2 are dose dependent in these vessels. Vasoconstriction occurred at lower doses (10–100 μM in mesenteric arteries) via a PGH2/TxA2 receptor-dependent mechanism, whereas vasodilatation predominated at concentrations above 0.3 mM via a K+ channel-mediated hyperpolarization (10). The present study shows that interstitial [H2O2] ranges between 50 and 300 nM. Even after accounting for the 20–30% probe efficiency, levels are still well within the dose range that purportedly constricts vessels in other tissues. Indeed, acute studies in our laboratory have shown that infusion of H2O2 in medullarydialysates from 116 to 211 nM decreased medullary blood flow, urinary sodium excretion, and urine volume, suggesting that a physiological increase of H2O2 produces vasoconstric-

We conclude that elevation of H2O2 in the renal medulla of SS rats plays an important role in salt-induced hypertension and renal injury, and therapies that reduce both O2•− and H2O2 should prove to be more effective in the long-term treatment of hypertension.
