Submitted 30 July 2009; accepted in final form 7 February 2010

Cummings BP, Stanhope KL, Graham JL, Evans JL, Baskin DG, Griffen SC, Havel PJ. Dietary fructose accelerates the development of diabetes in UCD-T2DM rats: amelioration by the antioxidant, α-lipoic acid. Am J Physiol Regul Integr Comp Physiol 298: R1343–R1350, 2010. First published February 10, 2010; doi:10.1152/ajpregu.00468.2009.—Sustained fructose consumption has been shown to decrease insulin sensitivity, increase inflammation, and promote dyslipidemia, (18, 37–39, 44, 45) and may thereby increase the risk for development of Type 2 diabetes mellitus (T2DM). Fructose has also been demonstrated to increase reactive oxygen stress (3, 14, 15, 26, 46, 47), which may contribute to insulin resistance, islet dysfunction and the development of T2DM (10–12).

Thus, we hypothesized that sustained fructose consumption would accelerate the onset of T2DM in University of California, Davis (UCD)-T2DM rats, a model of T2DM that is more similar in etiology to T2DM in humans than other existing rodent models (4).

Because of the increasing prevalence of T2DM, there is a need to identify new effective strategies for diabetes prevention, including the potential use of nutritional supplements. Alpha-lipoic acid (LA) is a widely used nutritional supplement that has antioxidant properties and other insulin-sensitizing actions (9, 13, 23, 25, 29). LA is a potent, multifunctional mitochondrial antioxidant with a unique self-regenerating capacity (1, 28, 43). LA scavenges reactive oxygen species (ROS), reduces other antioxidants such as vitamins E and C, chelates metals and repairs oxidized proteins, reduces inflammation and acts as a cofactor for mitochondrial enzymes responsible for glucose oxidation such as pyruvate dehydrogenase (29, 33). Furthermore, LA treatment has been reported to improve insulin sensitivity in rodent models (7, 25, 35, 36, 46) and in obese and diabetic humans (19, 24, 30, 31).

We hypothesized that daily LA supplementation would reduce oxidative stress and ameliorate the accelerated onset of T2DM in fructose-fed UCD-T2DM rats. Thus, we determined the time to diabetes onset and assessed oxidative status and changes of glucose tolerance, glucose-stimulated insulin secretion, and circulating lipids and hormones in three groups of UCD-T2DM rats: control (chow-fed), fructose-fed (20% of energy), and fructose + LA (20% of energy from fructose + 80 mg LA·kg body wt$^{-1}$·day$^{-1}$).

METHODS

Diets and animals. The UCD-T2DM rat model was derived by crossing obese Sprague-Dawley rats prone to adult-onset obesity and insulin resistance (40, 42) with lean Zucker diabetic fatty (ZDF) rats that have intact leptin signaling, but a defect in pancreatic β-cell insulin gene transcription (17). This cross resulted in a new rat model that develops polygenic adult-onset obesity and diabetes in both sexes with animals exhibiting insulin resistance, impaired glucose tolerance, and eventual β-cell decompensation (4). These animals also demonstrate a later age of diabetes onset than other rodent models of T2DM, such as the ZDF rat, making them highly suitable for diabetes prevention studies (2, 4).

Male rats were housed in hanging wire cages in the animal facility in the Department of Nutrition at the University of California, Davis, and maintained on a 12:12-h light-dark cycle. Food intake and body weight were measured three times a week. Diabetes onset was defined as a fasting plasma glucose value $>125$ mg/dl. Animals were moni-
tored up to 1 yr of age for T2DM onset. The experimental protocols were approved by the UCD Institutional Animal Care and Use Committee.

Starting at 2 mo of age, male animals were divided into three groups: control (n = 23), fructose (n = 30), and fructose + LA (n = 28). Baseline body weights were 358 ± 4 g, 358 ± 4 g, and 360 ± 4 g in control, fructose, and fructose + LA animals, respectively. All animals received a ground rodent chow diet (no. 5012, Ralston Purina, Belmont, CA) supplemented with safflower oil, such that the percent energy from fat, protein, and carbohydrate were 27%, 17%, and 56%, respectively, for all treatment groups. The fructose and fructose + LA groups received fructose at 20% of energy. LA (racemic form; 1:1 ratio of the individual enantiomers; Antibioticos, Rodano, Italy) was mixed in with the chow to provide a dose of 80 mg LA/kg body wt⁻¹•day⁻¹. Blood samples were collected after an overnight fast into EDTA-treated tubes each month until 8 mo of age for measurement of glucose, insulin, triglyceride (TG), adiponectin, and leptin. Twelve-hour urine samples were also collected monthly in sodium azide-treated flasks and assayed for glucose. At 3.5 mo of age, an intravenous glucose tolerance test was conducted on unanesthetized animals. Animals were fasted overnight and a 27-gauge butterfly catheter was placed in the saphenous vein for infusion of a bolus dose of 500 mg/kg glucose administration. A subset of animals (n = 11 per group) were euthanized at 4 mo of age and tissues were collected for the analyses described below. Whole blood samples were also collected from this subset of animals at 2 and 4 mo of age for the measurement of reduced to oxidized glutathione ratio (GSH/GSSG) in erythrocytes as an index of oxidative capacity.

Pancreatic immunohistochemistry. Pancreata were dissected under pentobarbital sodium anesthesia and placed in 4% paraformaldehyde at 4°C and embedded in paraffin. Sections (6 μm thick) were treated with 0.3% hydrogen peroxide for 30 min, followed by 5% normal goat serum in PBS, and then immunostained following a standard protocol (48). Antibodies used were 1 monoclonal anti-insulin (Sigma I-2018; Sigma, St. Louis, MO) at 6 μg/ml and 2) monoclonal anti-glucagon (Sigma G-2654) at 10 μg/ml, 4°C overnight. Detection was by the ABC Elite kit (Vectorstain PK-6100; Vector Laboratories, Burlingame, CA) and diaminobenzidine-H₂O₂ (DAB) (Vector SK-4100), and counterstained in hematoxylin. For a negative control, normal mouse IgG was substituted (015-000-002; Jackson ImmunoResearch, Bar Harbor, ME) at 10 μg/ml, and the absence of staining of islet cells was confirmed. Images were captured using a Nikon Coolscope microscope at ×20 magnification. Original images of immunostained islets were captured as 16-bit RGB JPEG files. Each full original JPEG file was globally processed with the Auto Levels function of Adobe Photoshop to adjust color balance and contrast (no other manipulations were performed on the original image files).

Pancreatic insulin extraction. Pancreatic insulin was extracted using a combination of methods of Davidson and Haist (5), Dixit et al. (6), and Karam and Gordenky (21). Preweighed pancreas samples were minced and sonicated and then incubated overnight at 4°C in acid alcohol with aprotinin. Samples were centrifuged, and the supernatant was collected, and the pellet was washed once more with the same solution. An alcohol diethyl ether solution (38% alcohol, 62% ether) was added to the supernatants and incubated overnight at 4°C to precipitate the insulin. Samples were centrifuged, and the pellet was reconstituted in 0.01 N hydrochloric acid. Samples were analyzed for insulin content by RIA (Millipore, St. Charles, MO). One animal from the control group and one from the fructose group had become diabetic and started losing weight prior to euthanasia, and thus were excluded from the data set to avoid the confounding effects of weight loss on tissue TG content and adiposity.

Mesenteric adipocytes were isolated according to the method of Rodbell (32), as modified by Mueller et al. (27). Adipose tissue was minced and incubated with digestion buffer with collagenase at 37°C with gentle shaking for 30 min. The resulting cell suspension was diluted with 0.1 M HEPES-phosphate buffer and filtered through a 250-μm nylon mesh screen. The filtered cells were washed once and centrifuged at 1,000 rpm for 6 min. Immediately following centrifugation, 25 μl of packed adipocytes were added to an Accuvette containing 20 μl of Isoton (Beckman Coulter, Sykesville, MD). The Accuvette was immediately capped and gently invereted until the cells were uniformly dispersed. The Accuvette was quickly placed on the sampling platform of the MultiSizer III and a 0.5-ml aliquot was counted and sized through a 280-μm aperture. Using the Multisizer 3.51 software supplied with the Multisizer III, cells were counted and sorted into 300 size bins in a range of 12-1,200 pl. The percent of total adipocyte volume was calculated for each bin, and the maximum value was reported as the peak value.

Assays. Plasma and urine glucose were measured using an enzymatic colorimetric assay for glucose (Thermo DMA, Louisville, CO). Plasma TG was measured using an enzymatic colorimetric assay (L-type TG H kit, Wako Chemicals, Richmond, VA). Insulin, leptin, and adiponectin were measured with rodent/rat specific RIAs (Millipore). Plasma insulin in intravenous glucose tolerance test (IVGTT) samples was measured by rat/mouse insulin ELISA (Millipore) since small blood samples were collected (~200 μl blood per time point), preventing the use of RIA. Whole blood GSH and GSSG were measured using an enzymatic colorimetric assay (BIOXYTECH GSH/GSSG-412; Oxis Research, Portland, OR). Fasting plasma intracellular adhesion molecule 1 (ICAM-1) was measured with an ELISA for rat sICAM-1 (R&D Systems, Minneapolis, MN).

Statistics and data analysis. Data are presented as means ± SE. Statistical analyses were performed using GraphPad Prism 4.00 for Windows, GraphPad Software (San Diego, CA). Diabetes prevention was analyzed by Log-rank testing of Kaplan-Meier survival curves up to 8 mo of age since 18/19 fructose-fed animals were diabetic by this age. Longitudinal data were compared by two-factor repeated-measures ANOVA (time and treatment) followed by post hoc analysis with Bonferroni’s multiple-comparison test. Mesenteric adipose weights, mesenteric adipocyte size, and tissue TG results were analyzed by one-factor ANOVA. For IVGTT data, the area under the curve was calculated and compared by one-factor ANOVA. Inulin sensitivity was calculated by dividing the slope of the glucose curve between 5 and 30 min after glucose infusion by the insulin area under the curve times 1,000. The 4 mo GSH/GSSG ratios were compared with baseline values by Student’s t-test. Animals that did not complete the 8-mo time course were not included in longitudinal analyses. Differences were considered significant at P < 0.05.

| Table 1. Average ages of onset and incidence of diabetes in animals followed ≤1 yr of age |

RESULTS

Effects of fructose and LA on T2DM onset. Chronic consumption of the high-fructose diet accelerated diabetes onset ($P < 0.01$) with fructose animals developing fasting hyperglycemia (fasting plasma glucose $> 125$ mg/dl) $2.6 \pm 0.5$ mo earlier than control animals (Table 1). LA supplementation in fructose-fed rats delayed T2DM onset by $1.0 \pm 0.7$ mo compared with animals consuming fructose alone ($P < 0.05$) (Fig. 1). Despite these differences in T2DM onset, groups did not differ in energy intake or body weight (Fig. 2). At 4 mo of

Fig. 1. Kaplan-Meier analysis of diabetes incidence in control ($n = 12$), fructose ($n = 19$), and fructose + alpha-lipoic acid (LA) ($n = 17$) groups. *$P < 0.05$, **$P < 0.01$ by log-rank test compared with fructose.

Fig. 2. Weekly mean energy intake ($A$) and body weight ($B$) in control ($n = 12$), fructose ($n = 18$), and fructose + LA ($n = 16$) groups. Values are expressed as means $\pm$ SE.

Fig. 3. Plasma glucose ($A$), insulin ($B$), and triglycerides (TG) ($C$) excursions following intravenous glucose administration (500 mg/kg body wt, 50% dextrose solution) in control ($n = 15$), fructose ($n = 20$), and fructose + LA ($n = 18$) prediabetic rats at 3.5 mo of age. Values are expressed as means $\pm$ SE. *$P < 0.05$ compared with fructose, **$P < 0.05$ compared with control and fructose + LA, ***$P < 0.05$ compared with control by one-factor ANOVA. For TG values, control: $n = 13$, fructose: $n = 19$, fructose + LA: $n = 17$. 
age, average energy intake was control $= 109 \pm 3$ kcal/day, fructose $= 108 \pm 3$ kcal/day, fructose + LA $= 107 \pm 6$ kcal/day, and average body weights were control $= 578 \pm 16$ g, fructose $= 596 \pm 9$ g, fructose + LA $= 579 \pm 7$ g. There was a tendency for fructose rats to have higher energy intake starting at 6 mo of age. By this age, 16 of the 19 fructose-fed animals had developed diabetes and were, therefore, developing diabetic hyperphagia. Average urine glucose values at 6 mo of age were control $= 1,683 \pm 650$ mg/dl, fructose $= 3,080 \pm 723$ mg/dl, fructose + LA $= 1,735 \pm 574$ mg/dl.

Effects of fructose and alpha-lipoic acid on glucose tolerance and lipids. Insulin sensitivity (IS), as assessed by IVGTT, was significantly lower in fructose and fructose + LA animals compared with control animals (IS: control $= -0.42 \pm 0.11$, fructose $= -0.087 \pm 0.10$, fructose + LA $= -0.13 \pm 0.14$, $P < 0.05$). However, fructose + LA animals were able to maintain lower glucose excursions, similar to control animals, by increasing insulin secretion in response to glucose, resulting in larger insulin excursions [area under the curve (AUC) control $= 42,637 \pm 1,602$, fructose $= 48,760 \pm 2,027$, fructose + LA $= 41,234 \pm 1,561$ mg/dl $\times 180$ min, $P < 0.05$ fructose compared with control and fructose + LA] (Fig. 3A).

Insulin excursions between baseline and 60 min after glucose administration were higher in fructose + LA animals compared with fructose-fed animals (AUC: control $= 224 \pm 24$, fructose $= 215 \pm 17$, fructose + LA $= 277 \pm 33$ ng/ml $\times 60$ min, $P < 0.05$), suggestive of preservation of islet/β-cell function (Fig. 3B). TG exposure during IVGTT was increased in fructose-fed and fructose + LA groups compared with control (AUC: control $= 14,929 \pm 1,923$, fructose $= 21,680 \pm 2,269$, fructose + LA $= 22,987 \pm 2,381$ mg/dl $\times 180$ min, $P < 0.05$), further indicating the presence of insulin resistance in both the fructose and fructose + LA animals (Fig. 3C).

Longitudinal measurements of metabolites and hormones. Consistent with the observed delay in T2DM onset, fasting plasma glucose concentrations were significantly higher in fructose-fed animals compared with both control and fructose + LA animals, particularly at 8 mo of age, at which time 17 of the 19 fructose animals had developed overt diabetes (Fig. 4A, $P < 0.05$). Fructose consumption tended to result in higher fasting plasma insulin concentrations compared with control animals, and this effect was mitigated by simultaneous LA supplementation (Fig. 4B). Fasting plasma TG concentrations were almost twofold higher in fructose-fed animals compared with control animals at 4 mo of age ($P < 0.001$), whereas fasting plasma TG levels only tended to be elevated in fructose + LA animals.

Fig. 4. Monthly fasting plasma glucose (A), insulin (B), TG (C), adiponectin (D), and leptin (E) concentrations in control (n = 12), fructose (n = 18), and fructose + LA (n = 16) animals. Values are expressed as means ± SE. **P < 0.001 by Bonferroni’s posttest compared with control; *P < 0.05 by Bonferroni’s posttest compared with control and fructose + LA (A).***P < 0.001 by two-factor repeated measures ANOVA compared with control and fructose + LA; **P < 0.01 by two-factor repeated measures ANOVA compared with control (C).
compared with control (Fig. 4C). The majority of animals in the 
fructose group (11 out of 19) were prediabetic at this age, 
demonstrating the development of fasting hypertriglyceridemia 
prior to T2DM onset in fructose-fed rats. There were no 
significant differences in fasting plasma adiponectin or leptin 
concentrations between treatment groups over the course of the 
study (Fig. 4, D and E).

The GSH/GSSG ratio was significantly lowered compared 
with baseline values in fructose animals, but this ratio re- 
mained stable in both control and fructose + LA animals 
(\%ΔGSH/GSSG from initial: control = −9 ± 15, fructose = 
−19 ± 4, fructose + LA = −8 ± 7) (Table 2). Fasting plasma 
sICAM-1 concentrations were elevated in fructose-fed and 
fructose + LA rats compared with control rats at 5 mo of age 
but did not differ between fructose + LA and fructose-fed rats 
(Table 3).

Visceral adiposity and tissue TG content. Body weight, fat 
depot weights, organ weight, and mesenteric adipocyte size did 
not differ between groups (Table 4). Liver and muscle TG 
content did not differ between groups but tended to be higher 
in the fructose + LA group.

Pancreatic immunohistochemistry and insulin content. Im- 
munostaining for insulin and glucagon was performed on a 
subset of six animals per group to assess islet morphology. 
Fig. 5 presents representative images of control, fructose-fed, 
and fructose + LA-treated animals. Generally, islets from 
control and fructose + LA-treated animals appeared to be 
smaller with less infiltration than islets from animals that 
received the high-fructose diet alone. Despite these morpho-
logic differences, insulin content measured in pancreases from 
prediabetic animals killed at 4 mo of age was not different 
between groups (Table 3).

DISCUSSION

In this study, we demonstrated that chronic fructose con-
sumption accelerates the onset of diabetes by reducing insulin 
sensitivity and glucose tolerance and by promoting dyslipide-
emia, oxidative stress, and inflammation in UCD-T2DM rats. 
Furthermore, supplementation with LA in fructose-fed rats 
ameliorates the acceleration of diabetes onset and improves 
glucose tolerance, glucose-stimulated insulin secretion, and 
oxidative capacity, without decreasing body weight or affect-
ing triglycerides. Together, these results are supportive of an 
important role for oxidative stress in the ability of fructose to 
hasten the onset of diabetes in UCD-T2DM rats.

The mechanism by which sustained fructose consumption 
reduces insulin sensitivity and glucose tolerance, thus predis-
posing individuals to development of T2DM, is not estab-
lished. It has been suggested that fructose reduces insulin 
sensitivity by providing a direct source of intrahepatic triglyc-
eride via de novo lipogenesis (39, 41). Alternatively, it has also 
been suggested that fructose-induced hepatic insulin resistance 
is a product of increased hepatic stress signaling (47). Despite 
the observed increases of fasting plasma TG in response to 
fructose feeding, liver and muscle TG content were not in-
creased in fructose-fed UCD-T2DM rats. Thus, induction of 
oxidative stress is a potential mechanism by which dietary 
fructose decreases insulin sensitivity in UCD-T2DM rats. This 
is supported by the observation that the GSH/GSSG ratio 
was significantly decreased only in the animals consuming fructose 
without LA supplementation. GSH is a key metabolite in the 
maintenance of the cellular redox state, and GSSG is its 
oxidized counterpart. Thus, maintaining higher GSH relative 
to GSSG levels is important in the protection of cell membranes 
from free radicals (20). The loss in oxidative capacity may, in 
part, explain the observed decreases of glucose tolerance and 
inulin sensitivity in fructose-fed animals. Fructose consump-
tion has been reported to increase production of reactive 
metabolites, which can activate pathways, such as c-Jun-N-

Values are expressed as means ± SE; Control: n = 10, Fructose: n = 10, Fructose + LA: n = 11. For pancreatic insulin content, Control: n = 4, Fructose: n = 5, Fructose + LA: n = 5.
terminal kinase and nuclear factor-κB pathways that result in serine phosphorylation of the insulin receptor and insulin receptor substrate proteins, resulting in decreased insulin sensitivity (12). Furthermore, the lack of a compensatory increase of the insulin response to glucose during IVGTT in the animals consuming fructose alone suggests β-cell dysfunction, which may be a result of oxidative stress at the level of the islet/β-cell (10, 11). It has been well documented that elevated circulating lipids can increase oxidative stress in β-cells and that with impaired oxidative regenerative capacity, this can lead to β-cell dysfunction and damage (11).

A role for oxidative stress in the acceleration of T2DM onset by fructose consumption in the UCD-T2DM rat is further strengthened by the effects of LA treatment in fructose-fed rats. We used a lower dose of LA to investigate the antioxidant properties of LA in the presence of fructose-induced oxidative stress, independent of its previously reported effects to decrease food intake and body weight (23, 34, 36). As in the control group, the animals consuming fructose that received supplemental LA did not exhibit a significant decrease of the GSH/GSSG ratio after 2 mo of treatment. This improvement in oxidative capacity was reflected in the IVGTT profile, as fructose + LA animals were able to maintain glucose excursions similar to control animals via increased insulin responses during the first 60 min after intravenous glucose administration, despite the presence of insulin resistance induced by chronic fructose consumption. Thus, LA supplementation appears to improve glucose-stimulated insulin secretion in fructose-fed rats. The preservation of islet function was supported by pancreatic immunohistochemistry, in which smaller islets with less infiltration were observed in control animals and fructose-fed animals receiving LA compared with the animals consuming fructose alone. Furthermore, the delay in onset in the animals supplemented with LA cannot be attributed to improved insulin sensitivity. LA has been suggested to improve insulin sensitivity by decreasing ectopic TG deposition and increasing AMP kinase expression in some studies (25, 36). However, differences in muscle or liver TG content, mesenteric adipocyte size, and circulating adiponectin concentrations were not observed in the present study. It is possible that reductions of food intake and body weight gain reported with higher doses of LA contributed to the previously observed effects of LA to improve insulin sensitivity (25, 36).

Despite the widespread use of LA, only one other study has been conducted to assess the effects of LA to prevent/delay the onset of Type 2 diabetes (36). In this study, LA supplementation completely prevented diabetes onset (compared with 78% diabetes incidence in untreated rats) in Otsuka Long-Evans

Fig. 5. Representative images of pancreas sections from control, fructose-fed, and fructose + LA supplemented animals at 4 mo of age. Hematoxylin-and-eosin stain for control (A) fructose, (B) and fructose + LA (C). Anti-insulin immunostaining for control (D), fructose (E), fructose + LA animals (F). Anti-glucagon immunostaining for control (G), fructose (H), and fructose + LA (I).
Tokushima Fatty rats, a rat model in which obesity and diabetes are thought to result, in part, from a mutation in the gene encoding the CCK-A receptor (22). The present study was conducted in a rat model with polygenic adult-onset obesity and diabetes, which is more similar to the etiology of T2DM in human populations (4). Furthermore, this previous study (22) employed a substantially higher dose of LA (200 mg·kg body wt·day⁻¹), which resulted in decreases of both food intake and body weight.

In summary, fructose feeding accelerates the onset of Type 2 diabetes, and concurrently decreases glucose tolerance, insulin sensitivity, and oxidative capacity compared with UCD-T2DM rats fed a standard rodent chow diet. It would also be of interest to determine whether fructose feeding accelerates diabetes onset compared with a glucose-fed control group. Supplementation with the antioxidant, LA, attenuated many of the effects of fructose consumption. This observation is supportive of a role for oxidative stress in the effects of dietary fructose to induce insulin resistance and accelerate the development of diabetes. Together, these data indicate the need for additional investigation of effects of antioxidants, such as LA, on glucose metabolism and islet/β-cell function and the prevention of T2DM (8). The potential for antioxidants to delay the onset of T2DM in human populations is important since delaying the onset of diabetes by even a few years, would similarly delay the development of complications of diabetes, including retinopathy, nephropathy, neuropathy, and macrovascular disease.

ACKNOWLEDGMENTS

The immunohistochemistry work was done in the Molecular Imaging Core, University of Washington Diabetes Endocrinology Research Center. We thank Hong-Duc Ta, Sunhye Kim, and Riva Dill for their extensive help with animal care and monitoring and Joyce Murphy for her excellent technical support with pancreas immunohistochemistry. The authors are grateful to Medical Research Institute (San Francisco, CA) and, in particular, Edward Byrd, for generously donating the lipoic acid used in this study. We thank Susan Bennett, Cheryl Phillips, and the Meyer Hall Animal Facility staff for providing excellent animal care.

GRANTS

The immunohistochemistry data are the result of work supported by facilities at the Veterans Affairs (VA) Puget Sound Health Care System, Seattle, Washington. Dr. Baskin is Senior Research Career Scientist, Research and Development Service, Department of VA Puget Sound Health Care System, Seattle, WA. This research was supported, in part, by the National Institutes of Health (NIH) through Grant AT002993. Dr. Havel’s laboratory also receives support from NIH Grants R01 HL075675, R01 HL091333, AT002599, AT-002993, AT003645, and the American Diabetes Association. Immunohistochemistry work was supported by NIH National Institute of Diabetes and Digestive and Kidney Diseases Grant P30 DK-17047 through the Cellular and Molecular Imaging Core of the University of Washington Diabetes Endocrinology Research Center.

DISCLOSURES

Joseph L. Evans is a consultant for mRL, a company that distributes lipoic acid.
