Running Title: Insulin Physiologically Regulates Na⁺
Abstract

Despite the effects of insulinopenia in type 1 diabetes and evidence that insulin stimulates multiple renal sodium transporters, it is not known whether normal variation in plasma insulin regulates sodium homeostasis physiologically. This study tested whether the normal postprandial increase in plasma insulin significantly attenuates renal sodium and volume losses. Rats were instrumented with chronic artery and vein catheters, housed in metabolic cages, and connected to hydraulic swivels. Measurements of urine volume and sodium excretion (UNaV) over 24 hrs and the 4-hr postprandial period were made in Control (C) rats and Insulin-Clamped (IC) rats in which the postprandial increase in insulin was prevented. 24-hr urine volume (36±3 vs. 15±2 ml/day) and UNaV (3.0±0.2 vs. 2.5±0.2 mmol/day) were greater in the IC compared to C rats, respectively. Four hrs after rats were given a gel meal, blood glucose and urine volume were greater in IC rats, but UNaV decreased. To simulate a meal while controlling blood glucose, C and IC rats received a glucose bolus that yielded peak increases in blood glucose that were not different between groups. Urine volume (9.7±0.7 vs. 6.0±0.8 ml/4-hrs) and UNaV (0.50±0.08 vs. 0.20±0.06 mmol/4-hrs) were greater in the IC vs. C rats, respectively, over the 4 hr test. These data demonstrate that the normal increase in circulating insulin in response to hyperglycemia may be required to prevent excessive renal sodium and volume losses, and suggest that insulin may be a physiologic regulator of sodium balance.

Key Words: Insulin, sodium excretion, postprandial, urine volume
Insulin is well documented to stimulate sodium transport at sites all along the nephron. However, the physiologic significance of this effect is relatively unknown. Insulin-stimulated sodium chloride transport has been demonstrated in the renal proximal tubule (16, 33), loop of Henle (24), distal convoluted tubule (38), and cortical collecting duct (15, 41, 47, 48). It has been shown to activate several renal sodium transport mechanisms, including the epithelial Na\(^{+}\) channel (ENaC) (6, 13, 27, 34, 41), the Na\(^{+}\)-Cl co-transporter (NCC) (25), and the Na\(^{+}\)-K ATPase (15). Yet, current understanding basically is limited to the pathology defined by type 1 diabetes: If insulin is absent, renal sodium excretion increases dramatically, and when insulin is replaced the sodium loss is reversed. It is an all-or-none relationship that ascribes only pathologic significance to the sodium transport effects of insulin.

Because circulating glucose controls the release of insulin, the hormone levels vary throughout the day, especially with meals (21, 23). The postprandial increase in circulating insulin is critical for disposing of glucose and is known to control many aspects of intermediary metabolism. However, how these normal variations in circulating insulin modulate Na\(^{+}\) homeostasis remains largely undefined. Chronic hyperinsulinemia has been hypothesized to contribute to hypertension in obesity and type 2 diabetes through sodium-retaining actions (11). However, blood pressure data in human insulinoma patients (37, 44) and dogs with chronic insulin infusion (10, 18, 19) are not consistent with this hypothesis.
and do not address whether the normal variation in plasma insulin levels throughout the day significantly affects renal sodium excretion.

The association of insulin with meals has led to hypotheses that insulin may influence postprandial sodium excretion (2, 42), but that has not been tested experimentally. This study tested the hypothesis that the normal, postprandial increase in plasma insulin is important to prevent excessive urinary losses of salt and volume. If true, this would reveal a new physiologic role for insulin as part of the integrated control system that regulates sodium homeostasis. This hypothesis was tested by comparing the urine sodium and volume excretion responses to meals in control rats versus rats that were prevented from increasing plasma insulin above basal levels following a meal.

Methods

All animal studies were approved by the Institutional Animal Care and Use Committee of Augusta University. Male Sprague Dawley rats (350-400 g), purchased from Envigo (Madison, WI), were instrumented with abdominal aortic and femoral vein catheters using aseptic technique as described previously (3, 7-9). The catheters were exteriorized at the scapulae through a stainless steel button to which a 12-inch stainless steel spring was attached. The rats were housed in metabolic cages, and the spring was attached to a dual-channel Instech hydraulic swivel that enabled 24 hrs/day iv. infusion and undisturbed arterial blood sampling from the conscious rats as described previously (3, 7-9). Rats were maintained in a temperature- and light-controlled environment with a 12 hrs day/night cycle.
Rats had *ad libitum* access to food and water except when indicated in the experimental protocols, and were allowed at least 5 days for recovery from surgery and acclimation to the metabolic cages before the insulin clamp or control measurements were begun. Rats were maintained on normal sodium intake by feeding a sodium-deficient diet (Teklad CA.170950, Envigo, Madison, WI) and infusing saline 24 hrs/day iv. to deliver 2.5 mmol Na⁺/day as described previously (3, 7-9). The continuous iv. saline infusion also served as the vehicle for administering insulin to the rats with the insulin clamp.

**Insulin Clamp**

The chronic insulin clamp was designed to prevent circulating insulin levels from increasing in response to meals, while not completely eliminating insulin and creating overt type 1 diabetes. Rats were divided randomly into Control (C; n=18) and Insulin-Clamped (IC; n=15) groups, and randomly subdivided to have either the Postprandial or Glucose Bolus experiment come first, because only 8 rats were able to complete both procedures. Plasma insulin was clamped chronically in the IC period by first administering streptozotocin in sodium citrate buffer (STZ, 70 mg/kg, iv.) to impair endogenous insulin production. We have shown previously that STZ does not affect glomerular filtration rate (GFR), renal plasma flow, or MAP over the time frame of this study (7). After confirming hyperglycemia of at least 300 mg/dl (all rats achieved this by day 2 post STZ, averaging 402±27 mg/dl), 24 hr/day iv. insulin replacement was begun by adding insulin (porcine, Wockhardt, Wrexham, UK) to the daily iv. saline infusion. Arterial blood glucose was measured every morning from the chronically-implanted arterial catheter in every rat, and those data were used to determine the insulin dose needed each day to keep each IC rat at
the desired blood glucose level. The time required for rats to achieve stable glycemic
control was variable, ranging on average between 5-7 days. Once control was achieved,
the experimental protocols were begun. Control rats received only vehicle.

The initial goal of the IC clamp was to maintain fasting blood glucose in the normal range.
However, pilot studies revealed that if insulin replacement doses were set so that fasting
blood glucose in the IC rats matched that in the C rats, daily urine volume was
approximately 3-4 times greater. Therefore, insulin-replacement doses were raised so that
fasting blood glucose was lower in IC than C rats, in the hope of better matching baseline
regulation of salt and water balance between groups. The insulin dose that maintained
glucose control in these IC rats averaged 2.8±0.3 U/day. Based on the plasma insulin
data, part of the experiment was repeated in a different group of rats using a lower IC
insulin dose that averaged 1.6±0.1 U/day. The primary group of IC rats is referred to as IC
+ High Insulin Dosing (IC-High), and the follow-up group is referred to as IC + Low Insulin
Dosing (IC-Low).

**Experimental Protocols**

*24 hr assessment*

A 24-hr urine collection was made in C and IC-High rats under steady-state conditions and
*ad libitum* access to food and water. At the end of the 24-hr period, at approximately 10:00
a.m. and after food had been withdrawn for 2 hrs, an arterial blood sample was drawn for
measurement of blood glucose, plasma insulin, plasma renin activity (PRA), and glomerular
filtration rate (GFR).
Our hypothesis was that overnight meals would cause natriuresis and diuresis in IC-High rats that could not increase insulin in response to the meal, but there was no measure of the response to individual meals during ad libitum eating in the active nocturnal phase of the 24-hr period. Therefore, an acute postprandial experiment was run to measure the direct response to a meal. Approximately 5 days after previous measurements and blood sampling, rats were fasted 12 hrs overnight to encourage rapid consumption of a morning meal. At approximately 8:00 a.m. the next morning, each rat was given 11 grams of the veterinary supplement, Supplical (Butler Schein, Dublin, OH), which is a gel formulation that was used to facilitate rapid consumption. It is primarily a carbohydrate mixture (malt and corn syrups) with only 0.8% protein. This marked t=0 of a 4-hr postprandial urine collection. At the 2-hr mark, the food was removed and a blood sample was drawn to measure blood glucose, plasma insulin, and plasma renin activity.

Glucose Bolus

Because of the difficulty in matching Suppical intake and variation in blood glucose between groups during the acute meal, bolus glucose administration was used to simulate a meal with precise blood-glucose matching. This experiment was performed approximately 5 days after previous measurements and blood sampling. Food was removed from all rats at approximately 8:00 a.m. Four hrs later, a blood sample was taken to measure blood glucose. Then, rats were injected with a glucose bolus (1 g/kg, C and 0.45 g/kg, IC-High). These doses were determined in pilot studies to yield peak blood
glucose levels that were not different between the C and IC-High groups, and the glucose was injected via the abdominal aortic catheter so as not to interfere with the continuous iv. insulin clamp infusion. This marked t=0 of a 4-hr urine collection. Blood glucose was measured immediately after injection and then at 5, 10, 20, 30, 40 and 50 mins. Plasma insulin was measured at t = 5 min. Because of this repeated blood sampling, PRA was not measured in this protocol. Additional glucose boluses, at the same dose, were given at 1, 2, and 3 hrs, to ensure a significant increase in urine output over the 4-hr period.

Analysis of Samples

Urine and blood glucose concentrations were measured with an Accu-chek Active glucose meter (Roche, New York, NY). Electrolyte concentrations were measured by atomic absorption (Perkin Elmer, Shelton, OH). Plasma insulin concentration was measured by ELISA (SPI Bio, Bertin Pharma, Montigny-le-Bretonneux, France). PRA was measured by radioimmunoassay (Diasorin, Stillwater, MN). GFR was measured by $^{125}$I-iothalamate clearance (Glofil, Iso-Tex Diagnostics, Inc., Friendswood, TX) after 24 hr. iv. infusion to reach steady state (4, 7-9). Because this method requires plasma $^{125}$I-iothalamate to be stable, GFR could not be measured during the postprandial or glucose bolus experiments.

Statistics

Results are presented as mean ± SE. All data were graphed using Graphpad Prism software. Student t-tests for unpaired groups comparing C to IC rats were performed.
Comparison of plasma insulin under the different conditions was made using ANOVA. A probability value less than 0.05 was considered to be significant.

**Results**

**24-hr assessment**

The rats that were not able to increase plasma insulin (IC-High) had significantly greater urine volume (36±3 vs. 15±2 ml/day) and sodium excretion (3.0±0.2 vs. 2.5±0.2 mmol/day) than the C rats over the 24-hr period (Fig. 1A and 1B). GFR and PRA, measured after the 24-hr collection following a 2-hr fast, were not different between groups (Table 1). Fractional excretion of sodium, calculated from the 24-hr urine collection and the 2-hr fasted GFR, also was not different, averaging 0.44+/-.04 vs. 0.49+/-.04 % in C vs. IC-High. The IC-High rats had significantly greater water (29±3 vs. 6±2 ml) and food (25±2 vs. 16±1 grams) intakes than the C rats, respectively. The food was not the source of the increased sodium excretion, however, because sodium intake was clamped at normal in both groups by feeding a sodium-deficient diet and infusing 0.9% saline iv. 24 hrs/day to maintain the same sodium intake in both groups. Uncontrolled diabetes also did not explain the diuretic and natriuretic responses in the IC-High rats, because fasting blood glucose trended lower in the IC-High vs. C rats (88±21 vs. 130±4 mg/dl, respectively, ns, Fig. 1C). Thus, the diuresis and natriuresis were independent of an increase in fasting blood glucose. Urinary potassium excretion was not measured, because the rat chow contained potassium, and our caging system with the infusion swivels cannot completely
prevent food electrolytes from contaminating the urine. There were no differences in plasma sodium or potassium concentrations between IC-High and C groups (Table 1).

Postprandial

Fasted IC-High and C rats consumed $6.1\pm1.2$ and $6.2\pm0.5$ grams of the gel diet, respectively. Similar to the 24-hr response (Fig. 1A), urine volume over the 4-hr postprandial measurement period was significantly greater in the IC-High compared to the C rats ($4.5\pm0.9$ vs. $2.7\pm0.2$ ml, respectively; Fig. 2A). Water intake was not different, averaging $3.6\pm0.8$ and $3.8\pm0.9$ ml in IC-High and C rats, respectively, over the 4-hr period. However, urinary sodium excretion was significantly lower during the postprandial period in the IC-High vs. C rats (Fig. 2B), which was opposite the response measured over 24 hrs (Figure 1B). Blood glucose concentration was greater in the IC-High vs. C rats (Fig. 2C), and urine glucose excretion was significantly greater in the IC-High rats ($4\pm1\,\mu g/min$) vs. C rats (no glucose detectable in the urine). Urinary ADH secretion was significantly lower in IC-High vs. C rats, and PRA, plasma sodium concentration, and plasma potassium concentration were not different between groups (Table 1).

Glucose Bolus

Figure 3A shows that peak blood glucose responses were not different between the IC-High and C rats in response to the bolus glucose injections. Under these conditions, urine volume and urinary sodium excretion both were significantly greater over the 4-hr period in the rats that could not increase plasma insulin from baseline (IC-High) vs. C rats (Fig. 3B.
Because there was no possibility for food to contaminate the urine in this experiment, urinary potassium excretion was measured. It averaged 0.20±0.02 vs. 0.23±0.03 mmol over the 4-hr period in IC-High vs. C rats, respectively, and was not different. Urinary ADH secretion was significantly greater in IC-High vs. C rats, and plasma sodium and potassium concentrations were not different between groups (Table 1).

**Plasma Insulin**

Figure 4 shows plasma insulin concentration in C and IC-High rats under the 3 experimental conditions. In the C rats (white bars), the gel diet increased plasma insulin above fasting levels, and there was a substantially greater insulin response to the glucose bolus. Because we did not measure the plasma insulin response to STZ alone, i.e. before the insulin clamp began, it cannot be guaranteed that all IC-High rats had no postprandial or post-glucose endogenous release of insulin. However, plasma insulin levels in the IC-High rats (black bars) 2 hours after the gel diet and 5 minutes after glucose bolus did not rise above that of 2-hr fasting levels, suggesting the IC-High procedure was effective in preventing endogenous insulin release. Fasting plasma insulin concentration in the IC-High rats was not significantly greater than in the C rats by ANOVA. However, Figure 4 clearly shows a tendency for it to be greater. This likely was because of the high insulin-replacement doses used to prevent markedly elevated urine volumes in the IC-High rats, as described in the Insulin Clamp procedure above. This insulin-replacement dose resulted in lower fasting blood glucose in the IC-High versus the C group (Figure 1), and 24-hr urine volume that was only approximately 2-fold greater (Figure 1) in the IC-High group.
Low insulin-dosing IC group

To test whether this insulin-replacement dosing regimen and high fasting plasma insulin levels in the IC-High rats (Figure 4) could have played a role in their unexpectedly lower sodium excretion response to the gel diet (Figure 2), an additional group of rats (n=6) was run under both C and IC conditions, using lower insulin-replacement dosing during the insulin clamp. These rats were instrumented similarly, and this essentially repeated the experiment shown in Figure 1, but with lower insulin dosing for the insulin clamp (1.6±0.1 vs. 2.8±0.3 U/day). Fasting plasma insulin during IC + Low Insulin Dosing indeed was lower, averaging 22±5 uU/ml compared with the fasted plasma levels of 78±12 uU/ml in the IC-High group as shown in Figure 4 (IC group, 2-hr fast). Fasting plasma insulin under Control conditions averaged 10±4 uU/ml in these rats, similar to the 16±4 uU/ml in the C group in Figure 4. Blood glucose in IC-Low rats no longer was lower than Control levels (Figure 5C) and actually was significantly higher than Control. Figure 5 panels A and B show the renal response in these rats over a 24-hr period. Consistent with our pilot studies, urine volume was approximately 3 times greater during IC-Low (91±10 ml for IC-Low in Figure 5 vs. 36±3 ml for IC-High in Figure 1). However, despite these differences, 24 hr urinary sodium excretion was significantly greater during IC-Low vs. Control (Figure 5), similar to the response shown in Figure 1 for IC-High. Figure 6 shows the response to the acute gel feeding experiment in these rats. Again, similar to the response shown for the IC-High group in Figure 2, the IC-Low rats had greater urine volume and lesser sodium excretion responses to the acute gel feeding. Thus, the insulin dosing levels used to induce the insulin clamp did not appear to explain either the 24-hr or immediate postprandial renal sodium excretion responses.
Discussion

The main finding of this study is that rats that were prevented from raising plasma insulin levels had significantly greater urine volume and urinary sodium excretion than control rats over 24 hrs of ad libitum eating. A high carbohydrate meal replicated the diuretic response, but not the natriuretic response. However, an injected glucose bolus, that matched peak glucose levels between groups, caused significantly greater urine volume and over twofold greater urinary sodium excretion over a 4-hr period. These data demonstrate that the normal increase in circulating insulin in response to hyperglycemia is required to prevent excessive renal sodium and volume losses, and suggest that insulin may be a physiologic regulator of sodium balance.

Because there is a considerable volume of literature demonstrating significant effects of insulin to increase sodium reabsorption at multiple nephron sites (15, 16, 24, 33, 38, 41, 47, 48) via stimulation of a variety of sodium transporters (6, 13, 15, 25, 27, 34, 41), it could be argued that insulin already is known to be a physiologic regulator of sodium balance. However, that conclusion is a priori because it is inference based primarily on what is known about insulin from type 1 diabetes. While type 1 diabetes indeed identified a requirement for insulin to prevent life-threatening natriuresis and diuresis, it simply documents that insulin must be present. The effects of insulin loss and replacement on renal excretion in type 1 diabetes do not quantify the independent roles of insulin versus
glucose and do not address the potential physiologic role of the normal daily variation of plasma insulin on renal sodium excretion.

Regarding the independent roles of low insulin versus high glucose in causing the natriuresis and diuresis in type 1 diabetes, it is conventionally accepted that these effects are due to the hyperglycemia, i.e. to an osmotic diuretic effect of glucose. DeFronzo hypothesized in 1981 (11) that the natriuresis and diuresis in type 1 diabetes could be due, at least in part, to the decrease in insulin and its sodium-retaining action, but that hypothesis had not been tested directly until recently. We demonstrated, in dogs with type 1 diabetes, that 6 days of sustained hyperglycemia (~ 400 mg/dl) did not cause sustained natriuresis and diuresis unless plasma insulin decreased below normal levels (28). Thus, the decrease in insulin, rather than the hyperglycemia, was the cause of the sustained natriuresis and diuresis, suggesting that baseline insulin exerted a powerful sodium-retaining effect. A subsequent study from our laboratory showed that this was due to direct renal actions of insulin (29).

However, those studies did not address whether normal, daily variation in plasma insulin levels have a significant influence on renal sodium handling. Insulin has been hypothesized to influence postprandial sodium excretion (2, 42), but that has not been tested experimentally. In the present study, we controlled the insulin response to meals to test directly the role of daily variations in insulin on renal sodium excretion. Insulin is known to increase in response to a mixed meal, and can be stimulated by the protein and lipid components in addition to carbohydrates (23). The normal insulin clamp developed for this
study (IC rats) was effective in preventing meals and bolus glucose administration from increasing plasma insulin above fasting levels. Over a 24-hr period, this caused significantly greater urinary sodium excretion and urine volume in the IC versus C rats. Our hypothesis ascribes this effect to the failure of insulin to increase after meals in the IC rats, but Figure 4 shows that fasting plasma insulin was higher in the IC rats than in the C rats (24 hr data are fasting levels). Ecelbarger's laboratory reported that distal nephron insulin receptors promote NO-mediated natriuresis (43). Thus, one explanation for the natriuresis and diuresis in the IC rats over 24 hours could have been activation of this mechanism by the fasting hyperinsulinemia. However, the data from our IC + Low Insulin Dosing group argue against that explanation.

Pilot studies showed that if the insulin replacement dose was set to keep fasting blood glucose in the IC rats comparable to that in the C rats, then daily urine volume was 3-4 fold elevated. Therefore, insulin-clamp dosing in the IC rats was increased to yield a slight fasting hypoglycemia (Figure 1C). Figures 1A and B show that these IC-High rats still had 2-fold greater urine volume and significantly greater sodium excretion over 24 hours. To determine whether the high insulin dosing for the insulin clamp in these rats affected our results, an additional group of rats was run in which the insulin-clamp dosing was lowered (IC-Low). The insulin-clamp dose in this group averaged almost 50% lower, and plasma insulin averaged approximately 70% lower, than the IC-High group shown in Figure 1. The results (Figure 5) show the markedly elevated 24 hr urine volumes, but still the significantly elevated urinary sodium excretion. Thus, the natriuretic response over 24 hours of insulin
clamp was not affected by changing the insulin-clamp insulin dose, therefore not supporting the possibility that high insulin dosing caused the increase in 24-hr sodium excretion.

The renal excretory response to a single meal was used to determine whether the 24-hr natriuretic and diuretic responses were due to the effects of meals during overnight *ad libitum* eating. The diuretic response to the gel diet in the IC versus C rats mirrored the 24-hr response. Unexpectedly, however, urinary sodium excretion was lower in IC rats, opposite from the 24-hr response. The IC-Low rats were added to test whether the renal response to the meal was influenced by the insulin dose used to establish the insulin clamp. The results do not support that, because the data in Figure 6 compared against Figure 2 show that the sodium excretion response to the meal was not altered. The fact that the gel diet did not match the macronutrient content of the daily rat chow, that the meal came after an overnight fast, and that blood glucose was different between IC and C rats after the gel meal, all could have affected the results and will need to be addressed in future studies.

The glucose bolus experiment was designed to simulate a meal while allowing us to directly control the rise in blood glucose between groups. Figure 3 shows that the peak hyperglycemic responses were not different between the two groups. Subsequent blood glucose levels tended to be lower in the IC rats over the rest of the post-infusion time period, possibly because they required a 50% lower glucose dose to achieve the same peak increase in blood glucose as the C rats. Thus, there was no evidence for a greater blood glucose level in the IC rats after a bolus glucose load; yet, the IC rats excreted
approximately twice as much sodium and volume over 4 hrs than the C rats. The fact that
the gel diet increased urine volume but lowered sodium excretion in the IC rats, whereas
both urine volume and sodium excretion increased after the glucose bolus, provides
evidence that the sodium excretion response to the glucose bolus was not a consequence
of increased urine volume. The regulation of urine volume under these conditions is
unclear. Table 1 shows that antidiuretic hormone (ADH) levels were greater in the IC rats,
suggesting that ADH did not contribute to the diuretic response to the glucose bolus.
However, ADH was lower after the gel meal in the IC rats, which also had a diuretic
response. Therefore, further studies will be needed to determine to what extent ADH may
have contributed to these results.

These results showed that hyperglycemia-induced natriuresis and diuresis were
significantly greater if the glucose-induced hyperinsulinemia was prevented. We
hypothesize that this was due to loss of the antinatriuretic effect of insulin that normally
would have occurred if it had been allowed to increase. We hypothesize further that this
explains the greater 24 hr sodium excretion in the IC rats, but we will need a different
approach than the gel diet to link the 24 hr response more directly to postprandial
antinatriuretic effects of insulin. The mechanism for the antinatriuretic action is not known.
All manipulations of insulin in this study were of circulating insulin, so it is possible that
central actions on the sympathetic nervous system could be involved (26, 31, 40).
However, we recently used chronic, renal artery insulin infusion in dogs with type 1
diabetes to show that the sustained effects of circulating insulin on renal sodium and
volume excretion (28) were due to intra-renal actions of insulin (29). As discussed above,
there are multiple sites along the nephron where insulin has been shown to act, but this study was not designed to probe that aspect of insulin action. Interestingly, however, because the sodium-retaining effect of intrarenal insulin infusion was measured in diabetic (29), but not normal (18, 29) dogs, this suggested that some renal interaction between glucose and insulin might be involved. It will be interesting in that regard for future studies to test whether insulin action on SGLT2 (16) might augment the stimulatory effects of glucose, or whether glucose can modulate the well-known effect of insulin on ENaC (6, 22, 41) in the postprandial period.

PERSPECTIVES

There has long been fascination with the body's ability to achieve sodium balance rapidly, and the focus has been predominantly on excretion of a salt load. The reason for that focus is not known, but could be based on the need to facilitate renal excretion of salt in pathological states such as hypertension and heart failure. Regardless, the literature is dominated by the study of natriuretic influences following a meal. The ability to eliminate an acute salt load has been attributed to many factors, such as withdrawal of the renin-angiotensin-aldosterone system (5, 36), increased natriuretic peptide (12, 39, 46), withdrawal of renal sympathetic nerve activity (32, 35), hemodynamic factors (20), and gut-derived hormones such as glucagon-like peptide (GLP1) (17), amylin, secretin, vasoactive intestinal peptide, glucagon and uroguanylin (14, 30, 45). However, salt is a precious commodity that has been scarce during human evolution (1), yet there is little evidence for
meal-induced hormones that function to conserve the salt in a meal by limiting its
elimination by the kidneys. Our data suggest this is a physiologic function of insulin, thus
possibly warranting placement of insulin alongside the many other neural, hormonal, and
hemodynamic factors already known to be important components of the control system for
normal salt and volume homeostasis.

</table>
A. Blood Glucose, mg/dL vs. Time (minutes)

B. Urine Volume, ml/4 hr

C. Na Excretion, mmol/4 hr
The graph shows the levels of insulin (in uU/ml) following different conditions: 2-hr Fast, 2-hr Meal, 5 min Glucose, and IC-High.

- **Control** group had a lower insulin level in all conditions compared to the **IC-High** group.
- The **IC-High** group showed a significant increase in insulin levels after a 2-hr Meal and a 5 min Glucose challenge.

Statistical significance is indicated by:
- A star (*) for the 2-hr Meal condition.
- A dollar sign ($) for the 5 min Glucose condition.

The graph illustrates that the IC-High condition results in a higher insulin response, particularly noticeable in the 5 min Glucose condition.
**A.**

Urine Volume, ml/4 hr

**B.**

Na Excretion, mmol/4 hr

**C.**

2-hr Post Meal Blood Glucose, mg/dL

Control | IC-Low
